Abstract

Our paper examines the impact of heterogeneous trading technologies for households on asset prices and the distribution of wealth. We distinguish between passive traders who hold fixed portfolios of stocks and bonds, and active traders who adjust their portfolios to changes in the investment opportunity set. To solve the model, we develop a new method that relies on an optimal consumption sharing rule that does not depend on the trading technology. As a result, we can derive an aggregation result for state prices, allowing us to solve for equilibrium prices and allocations without having to search for market-clearing prices in each asset market separately. We show that the fraction of total wealth held by active traders, not the fraction held by all participants, is critical for asset prices, because only these traders respond to variation in state prices and hence absorb the residual aggregate risk created by non-participants. We calibrate the heterogeneity in trading technologies to match the equity premium and the risk-free rate. The calibrated model reproduces the skewness and kurtosis of the wealth distribution in the data.

1 Introduction

Incomplete market models in which all households can only trade a limited menu of tradeable assets were initially embraced to explain the strong correlation in the data between household consumption and income. However, the actual menu of assets that household can trade is very rich. At the same time, there is a growing body of empirical evidence that different households behave as if they had access to different menus of tradeable assets. A majority of households does not invest directly in equity, in spite of the sizeable historical equity premium, but even among those who participate in equity markets, sophisticated investors invest a larger share of their wealth in equity and realize higher returns, while less sophisticated investors take a more cautious approach. As a result, sophisticated investors load up on aggregate consumption risk. The consumption of the 10% wealthiest households is five times more exposed to aggregate consumption growth than that of the average US household (Parker and Vissing-Jorgensen (2009)).

These empirical findings lead us to introduce heterogeneous trading technologies in an otherwise standard incomplete markets model. To solve this model, we develop a new method that does not rely on a price adjustment algorithm to clear each asset market separately. We introduce heterogeneity in trading technologies into an endowment economy with a large number of agents who are subject to both aggregate and idiosyncratic shocks, and who have CRRA preferences with coefficient $\alpha$. Our model distinguishes between passive traders, who trade fixed-weighted portfolios of bonds and equities, and active traders, who optimally re-adjust their portfolio holdings over time. We capture the differences in trading technologies by imposing different measurability restrictions on the household’s time-zero trading problem. These restrictions govern how net wealth is allowed to vary across different states of the world. We use the multipliers on these constraints to derive a consumption sharing rule for households and an analytical expression for the stochastic discount factor. Importantly, the household’s consumption sharing rule does not depend on the trading technology, only the dynamics of the multipliers do. The equilibrium stochastic discount factor only depends on aggregate consumption growth and a weighted average of these multipliers—the $-1/\alpha$-th moment. We refer to this simply as the aggregate multiplier.

In our approach, this household multiplier is a new state variable that replaces wealth. We characterize its dynamics by means of a simple updating rule that depends on the trading technology of the household. The individual’s multiplier updating rule and the implied updating rule for the aggregate multipliers completely characterize equilibrium allocations and prices. In continuous-time finance, Cuoco and He (2001) and Basak and Cuoco (1998a) used stochastic weighting schemes to characterize allocations and prices. Our approach differs because it provides a tractable and computationally efficient algorithm for computing equilibria in environments with a large number of agents subject to idiosyncratic risk as well as aggregate risk, and heterogeneity in trading op-

---

1Campbell (2006) refers to the body of literature that documents this heterogeneity as “household finance”.
opportunities. The use of cumulative multipliers in solving macro-economic equilibrium models was pioneered by Kehoe and Perri (2002), building on earlier work by Marcet and Marimon (1999). Our use of measurability constraints to capture portfolio restrictions is similar to that in Aiyagari, Marcet, Sargent, and Seppala (2002) and Lustig, Sleet, and Yeltekin (2007), who consider an optimal taxation problem, while the aggregation result extends that in Chien and Lustig (2006) to an incomplete markets environment.

Our paper is closely related to work by Krusell and Smith (1997) and (1998). Krusell and Smith (1998) consider a production economy with a large number of agents in which individual labor supply is subject to exogenous idiosyncratic shocks, while the aggregate production function is subject to aggregate productivity shocks. Households in this economy only trade claims to the physical capital stock. In this model with a single asset, KS only need to solve a forecasting problem for the return on capital. Similarly, we solve a forecasting problem for the growth rate of this aggregate multiplier. However, as soon as KS add an additional asset (e.g. a risk-free bond in Krusell and Smith (1997)), KS need to solve for the market-clearing pricing function for this asset. Applying this KS method in our model would require searching for a new pricing function for each additional aggregate state in each iteration, not knowing the mapping from the wealth distribution to state prices. Our aggregation result implies that we only need to forecast a single moment of the multiplier distribution, regardless of the number and the nature of the different trading technologies. We can directly compute the pricing kernel as a function of this moment. Hence, there is no need to search for the vector of state prices that clears the various asset markets. Finally, solving for the multiplier updating rule turns out to be simpler and faster than solving the household’s Bellman equation or consumption Euler equation.

We apply our method in a calibrated version of the model. To capture the richness of observed trading behavior in the data, we distinguish between passive traders who hold no stocks, the non-participants, and buy-and-hold passive traders who can only trade the market portfolio, i.e. a claim to aggregate consumption. The heterogeneity in trading technologies is calibrated to match the equity risk premium and the risk-free rate for a risk aversion coefficient of five, but, as an out-of-sample check, we show that the model also matches the relation between wealth and equity holdings in the data.

The interaction between a small segment of active traders and a larger segment of passive traders improves the model’s match with asset prices in the data along two dimensions: the first and second moments of risk premia. First, due to this interaction, equilibrium state prices are highly volatile and counter-cyclical, which delivers a larger average equity premium, but the conditional expectation of state prices—and hence the risk-free rate—is not. Instead, the equilibrium state prices are highly volatile across aggregate states. The non-participants create residual aggregate

---

Storesletten, Telmer, and Yaron (2007) implement this procedure in an OLG model with trading in capital and risk-free bonds.
risk that ends up being absorbed only by the active traders, not by the buy-and-hold traders. The non-participants create residual aggregate risk, because they consume “too much” in low aggregate consumption growth states (recessions) and “too little” in high aggregate consumption growth states (expansions). On the other hand, the active traders concentrate their consumption in “cheap” aggregate states (states with low state prices for aggregate consumption). Hence, to clear the goods market, the equilibrium state prices have to be much higher in recessions to induce a small segment of active traders to consume less, and much lower in expansions to induce them to consume more.

Second, the model endogenously generates counter-cyclical variation in risk premia, even though the aggregate consumption growth shocks are i.i.d. The share of total wealth owned by the active traders declines in low aggregate consumption growth states, because they take highly leveraged equity positions. As a result, the conditional volatility of state prices increases after each recession since a larger adjustment in state prices is needed to induce the smaller mass of active traders to clear the goods markets. As we increase the equity share in the passive trader portfolios, the second channel actually strengthens, and the volatility of risk premia increases, even though the first channel weakens, and average risk premia decline.

Our quantitative results contribute to a growing literature on the asset pricing impact of limited stock market participation, starting with Saito (1996), Basak and Cuoco (1998b) and Vissing-Jorgensen (2002), and more recently, by Guvenen (2003) and Gomes and Michaelides (2008).3 Overall, the consensus in the literature is that stockholders hold too much wealth in the data to fully explain the size of risk premia only by means of the limited participation mechanism. Our paper strengthens the limited participation explanation by showing that it is really the fraction of wealth held by active investors that matters, not the fraction of wealth held by all participants. In our calibrated model, more than half of the increase in the equity premium relative to the complete markets case is due to the heterogeneity in trading technologies in our model, rather than limited participation. At the same time, our model matches the asset share distribution in the data closely, while the limited participation benchmark cannot match the concentration of equity holdings in the data. More importantly, the heterogeneity in trading technologies more than doubles volatility of the market price of risk, relative to the limited participation benchmark, and this volatility amplification does not disappear as we increase the equity holdings of passive investors.

In our model, the consumption of passive traders is more exposed to idiosyncratic risk, because they fail to accumulate enough wealth to self-insure, while the consumption of active traders is more exposed to aggregate risk. This heterogeneity in the responsiveness of consumption to aggregate

3Guvenen (2003) argues that limited participation goes a long way towards explaining the equity premium in a model with a bond-only investor and a stockholder. We put Guvenen’s mechanism to work in a richer model with idiosyncratic risk, and with heterogeneity in trading technologies among market participants. In more recent work, Gomes and Michaelides (2008) also consider a model with bond-and stockholders, but they add idiosyncratic risk.
shocks in the model is consistent with recent evidence by Malloy, Moskowitz, and Vissing-Jorgensen (2007), who find that wealthier stockholders have consumption that is much more exposed to aggregate shocks. The active traders in our model realize much higher returns, as documented by Calvet, Campbell, and Sodini (2007), and they adopt a sophisticated trading strategy that exploits the time variation in the risk premium to do so. In the calibrated model, they accumulate on average three times more wealth than the average household in our model, because of their superior trading technology. This mechanism allows our model to match the skewness and kurtosis of the wealth distribution in the data, but it falls short of matching the left tail of the wealth distribution. Since these active traders are wealthy on average and since they have a high fraction of equities in their portfolio, the calibrated model delivers a closer match between wealth and equity shares in the data.

This paper is organized as follows. Section 2 describes the environment, the preferences and trading technologies for all households. Section 3 characterizes the equilibrium allocations and prices using cumulative multipliers that record all the binding measurability and solvency constraints. Section 4 describes a recursive version of this problem that we can actually solve. This section also describes conditions under which market segmentation does not affect the risk premium. In section 5 we study a calibrated version of our economy, section 6 does a number of sensitivity experiments: (i) we increase the participation rate to 50%, which reduces the equity premium by 80 basis points, and we compare the current asset share and wealth distribution in the data to the the model’s, (ii) we compare our model’s predictions to that of a model with only limited participation, without heterogeneity in trading technologies, (iii) we change the composition of the passive trader segment to show that only the average equity holdings of passive traders matters for the asset pricing results, and (iv) we change the calibration of aggregate and idiosyncratic shocks. All the proofs are in the appendix. A separate appendix with auxiliary results is available from the authors’ web sites. We have also made the matlab code available on-line.

2 Model

In this section we describe the environment, and we describe the household problem for each of the different asset trading technologies. We also define an equilibrium for this economy.

2.1 Environment

This is an endowment economy with a unit measure of households who are subject to both aggregate and idiosyncratic income shocks. Households are ex ante identical, except for the access to trading technologies. Ex post, the households differ in terms of their idiosyncratic income

\[\text{http://hlustig2001.squarespace.com/}\]
shock realizations. All of the households face the same stochastic process for these shocks, and all households start with the same present value of tradeable wealth.

In the model time is discrete, infinite, and indexed by \( t = 0, 1, 2, \ldots \). The first period, \( t = 0 \), is a planning period in which financial contracting takes place. We use \( z_t \in Z \) to denote the aggregate shock in period \( t \) and \( \eta_t \in N \) to denote the idiosyncratic shock in period \( t \). \( z^t \) denotes the history of aggregate shocks, and, similarly, \( \eta^t \), denotes the history of idiosyncratic shocks for a household. The idiosyncratic events \( \eta \) are i.i.d. across households. We use \( \pi(z^t, \eta^t) \) to denote the unconditional probability of state \((z^t, \eta^t)\) being realized. The events are first-order Markov, and we assume that \( \pi(z_{t+1}, \eta_{t+1}|z_t, \eta_t) = \pi(z_{t+1}|z_t)\pi(\eta_{t+1}|z_{t+1}, \eta_t) \).

Since we can appeal to a law of large number, \( \pi(z_t, \eta_t)/\pi(z^t) \) also denotes the fraction of agents in state \( z^t \) that have drawn a history \( \eta^t \). We use \( \pi(\eta_t|z^t) \) to denote that fraction.

There is a single final good in each period, and the amount of it is given by \( Y(z^t) \), which evolves according to \( Y(z^t) = \exp\{z_t\}Y(z^{t-1}) \), with \( Y(z^1) = \exp\{z_1\} \). This endowment good comes in two forms. The first form is diversifiable income, which is not subject to the idiosyncratic shock, and is given by \((1-\gamma)Y(z^t)\). The other form is non-diversifiable income which is subject to idiosyncratic risk and is given by \( \gamma Y(z^t)\eta_t \); hence \( \gamma \) is the share of income that is non-diversifiable.

All households are infinitely lived and rank stochastic consumption streams \( \{c(z^t, \eta^t)\} \) according to the following criterion

\[
U(c) = E \left\{ \sum_{t \geq 1} \beta^t \pi(z^t, \eta^t) \frac{c(z^t, \eta^t)^{1-\alpha}}{1-\alpha} \right\},
\] (2.1)

where \( \alpha > 0 \) denotes the coefficient of relative risk aversion, and \( c(z^t, \eta^t) \) denotes the household’s consumption in state \((z^t, \eta^t)\).

### 2.2 Asset Trading Technologies and Assets Traded

All households are endowed with a claim to their per capita share of both diversifiable and non-diversifiable income. Households cannot directly trade their claim to non-diversifiable income.

Households trade assets in securities markets and they trade the final good in spot markets that re-open in every period. All of the households have access to only one of three asset trading technologies. We assume households cannot switch between technologies. The active traders can trade a complete menu of claims whose payoffs are contingent on the aggregate state \( z^t \). The other
households are passive traders who can only trade a fixed-weighted portfolio of bonds and stocks.

In our model, equity is a leveraged claim to consumption, following Abel (1999). Let \( \phi \) denote the leverage parameter, let \( b_t(z') \) denote the supply of one-period risk-free bonds, and let \( R_t(z) \) denote the risk-free rate. We can decompose the aggregate payout that flows from the diversifiable income claim \((1 - \gamma)Y(z)\) into a dividend component \( d_t(z) \) from equity and a bond component \( R_t(z-1)b(z-1) - b(z) \). The bond supply adjusts in each node \( z' \) to ensure that the bond/equity ratio equals \( \phi \): \( b(z') = \phi [\omega(z') - b(z')] \) for all \( z' \), where \( \omega(z') \) denotes the price of a claim to aggregate consumption.

2.3 Measurability Constraints

To model these trading technologies, we will make use of measurability constraints, a different one for each trading technology. The rest of the household constraints are standard.

We use \( q\left( \left[ (z^{t+1}, \eta^{t+1}), (z^t, \eta^t) \right] \right) \) to denote the price of a unit claim to the final good in state \((z^{t+1}, \eta^{t+1})\) acquired in state \((z^t, \eta^t)\). The absence of arbitrage implies that there exist aggregate state prices \( q(z_{t+1}, z^t) \) such that \( q\left( \left[ (z^{t+1}, \eta^{t+1}), (z^t, \eta^t) \right] \right) = \pi(\eta^{t+1}|z^{t+1}, \eta^t)q(z_{t+1}, z^t) \), where \( q(z_{t+1}, z^t) \) denotes the price of a unit of the final good in aggregate state \( z^{t+1} \) given that we are in aggregate history \( z^t \).

Each household can trade both a complete set of contingent bonds. The budget constraint for this trader in state \((z^t, \eta^t)\) is:

\[
\gamma Y(z^t)\eta_t + a_{t-1}(z^t, \eta^t) - c(z^t, \eta^t) \geq \sum_{z^{t+1} \succ z^t} q(z_{t+1}, z^t) \sum_{\eta^{t+1} \succ \eta^t} a_t(z^{t+1}, \eta^{t+1})\pi(\eta^{t+1}|z^{t+1}, \eta^t) \tag{2.2}
\]

where \( a_{t-1}(z^t, \eta^t) \) denotes the number of unit claims to the final good purchased at \( t - 1 \) for state \((z^t, \eta^t)\), and \( a_t(z^{t+1}, \eta^{t+1}) \) denotes the number of goods purchased for delivery in state \((z^{t+1}, \eta^{t+1})\), where \((z^{t+1}, \eta^{t+1}) \succ (z^t, \eta^t)\). The period 0 spot budget constraint is given by

\[
a_{-1}(z_0) \geq \sum_{z_1} q(z_1, z^0) \sum_{\eta_1} a_0(z_1, \eta_1)\pi(\eta^{t+1}|z^{t+1}, \eta^t), \tag{2.3}
\]

where \( z^0 \) and \( \eta^0 \) are degenerate states representing the initial position in the planning state at time 0 before any of the shocks have been realized and where \( q(z_1, z^0) \) denotes the price in this stage of a claim to consumption in period 1.

In addition to their spot budget constraint, these traders also face a lower bound on the value of their net asset position:

\[
a_t(z^{t+1}, \eta^{t+1}) \geq M(\eta^{t+1}, z^{t+1}). \tag{2.4}
\]
Active traders  The active traders face the additional constraint that \( a_{t-1}(z^t, \eta^t) \) be measurable with respect to \( (z^t, \eta^{t-1}) \):

\[
a_{t-1}(z^t, [\eta^{t-1}, \eta_t]) = a_{t-1}(z^t, [\eta^{t-1}, \tilde{\eta}_t]),
\]

for all \( z^t, \eta^{t-1} \), and \( \eta_t, \tilde{\eta}_t \in N \). We refer this as the active trader’s measurability condition.

The active trader’s problem is to choose \( \{c(z^t, \eta^t), a_t(z^{t+1}, \eta^{t+1})\} \), \( a_0(z^1, \eta^1) \) to maximize his expected utility \( (2.1) \) subject to the constraints in \( (2.2)(2.4) \) and the measurability constraint in \( (2.5) \).

Passive traders  Let \( R^p(\varpi, z^t) \) denote the return on the passive trader’s total portfolio with fixed weight \( \varpi \) for equities. We can state the passive trader’s measurability condition as:

\[
a_{t-1}([z^{t-1}, z_t], [\eta^{t-1}, \eta_t]) = a_{t-1}([z^{t-1}, \tilde{z}_t], [\eta^{t-1}, \tilde{\eta}_t]),
\]

(2.6)

for all \( z^{t-1}, \eta^{t-1}, z_t, \tilde{z}_t \in Z \), and \( \eta_t, \tilde{\eta}_t \in N \).

The passive trader’s problem is to choose \( \{c(z^t, \eta^t), a_t(z^{t+1}, \eta^{t+1})\} \), \( a_0(z^1, \eta^1) \) to maximize his expected utility \( (2.1) \) subject to the constraints in \( (2.2)(2.4) \) and the measurability constraint in \( (2.6) \).

We distinguish between two types of passive traders: non-participants, who invest in the risk-free one-period bond, and buy-and-hold traders, who hold the market. The portfolio return of the non-participant (\( \varpi = 0 \)) is the risk-free rate: \( R^p(0, z^t) = R^f(z^{t-1}) \) is the risk-free rate. The portfolio return of the buy-and-hold trader is the return on a portfolio with \( \varpi \) invested in equities: \( R^p(\varpi, z^t) = R(z^t) \). In the quantitative section, we choose \( \varpi \) for the buy-and-hold traders such that they hold the market portfolio, i.e. a claim to aggregate consumption.

Importantly, the active traders can fully hedge against aggregate shocks. We can think of them as having access to a menu of stocks and bonds that is rich enough to span the aggregate shocks. In our quantitative analysis, since we have only two aggregate states, active traders are effectively trading the aggregate stock market and the bond. The passive traders cannot fully hedge against either aggregate or idiosyncratic risk.

2.4 Equilibrium

A fraction \( \mu_z \) of households are active traders. The other households are passive traders who can only trade a fixed-weighted portfolio of bonds and stocks. A fraction \( \mu_{bh} \) of passive traders, the buy-and-hold traders, can only trade a fixed-weighted portfolio of stocks and bonds, and a fraction \( \mu_{np} \), the non-participants, can trade only bonds. The market clearing condition in the contingent
bond market in each aggregate state $z^t$ is given by:

$$
\sum_{\eta^t} \sum_{\eta^{t+1}} \pi(\eta^{t+1}|z^{t+1}) \left[ \mu_{a_{t-1}}(z^t, \eta^t) + \mu_{a_{bh}}(z^t, \eta^t) + \mu_{a_{np}}(z^t, \eta^t) \right] = (1 - \gamma)Y(z^t),
$$

where $a^z$, $a^h$, and $a^{np}$ denote the bond holdings of the active traders, the buy-and-hold traders and the non-participants respectively.

**Definition 2.1.** A sequential equilibrium for this economy is defined in the standard way. It consists of a list of contingent bond holdings $\{a_{t-1}^j(z^t, \eta^t)\}$, $j \in \{z, bh, np\}$, a consumption allocation $\{c_{t-1}^j(z^t, \eta^t)\}$, $j \in \{z, bh, np\}$, and a list of contingent bond prices $\{q(z_{t+1}, z^t)\}$ such that: (i) given these prices, a household’s asset and consumption choices maximize her expected utility subject to the budget constraints, the solvency constraints and the measurability constraints for her trading technology $j \in \{z, bh, np\}$, and (ii) the contingent bond market clears in each node $z^t$.

**Other Trading Technologies** While we restrict ourselves to three trading technologies, our framework is flexible enough to handle other trading technologies. The most obvious active technology is the *complete markets* one which allows for trading bonds contingent on both aggregate and idiosyncratic shock realizations. In this case, there is no measurability constraint. Another active technology precludes direct trade in state contingent bonds, but it allows for optimally choosing the portfolio of equities and non-contingent bonds in each period. Since this trader’s financial wealth tomorrow is determined by his savings and portfolio choice today $\varpi(z^t, \eta^t)$, he still faces the same measurability restriction as the passive trader (see equation (2.6)). However, the ability to optimally choose $\varpi(z^t, \eta^t)$ introduces an additional first-order condition of the form

$$
\sum_{z^{t+1}|z^t, \eta^{t+1}|\eta^t} \nu(z^{t+1}, \eta^{t+1}) \frac{d}{d\omega} R^\omega(\varpi(z^t, \eta^t), z^{t+1}) \pi(z^{t+1}, \eta^{t+1}) P(z^{t+1}) = 0.
$$

This condition implies that he is choosing $\varpi(z^t, \eta^t)$ to relax his measurability constraint as much as possible. In the case with only two aggregate states that we consider in the quantitative section, there is of course no difference between this stock/bond trading technology and the active trading technology we consider in our paper.

There are limits to what the method can handle. It cannot easily handle problems that involve transaction costs (e.g. bid ask spreads), especially if they are not symmetric across all assets, or endogenous switching between different trading technologies. The next section analytically characterizes the household consumption function and the equilibrium pricing kernel in terms of the distribution of the household’s stochastic multipliers.
3 Solving for Equilibrium Allocations and Prices

This section reformulates the household’s problem in terms of a single present-value budget constraint, and sequences of measurability constraints and solvency constraints. We show how to use the cumulative multipliers on these constraints in the saddle point problem as stochastic weights that fully characterize equilibrium allocations and prices. Cuoco and He (2001) were the first to use a similar stochastic weighting scheme in a discrete-time setup.

From these contingent bond prices in the sequential equilibrium, we can back out the state prices recursively as follows:

\[
\pi(z^t, \eta^t) P(z^t, \eta^t) = q(z_t, z_{t-1}) q(z_{t-1}, z_{t-2}) \cdots q(z_1, z_0) q(z_0).
\]

(3.1)

We use \( \tilde{P}(z^t, \eta^t) \) to denote the Arrow-Debreu prices \( P(z^t) \pi(z^t, \eta^t) \). Let \( m(z^t+1|z^t) = P(z^t+1)/P(z^t) \) denote the stochastic discount factor that prices any random payoffs. We assume there is always a non-zero measure of active traders to guarantee the uniqueness of the stochastic discount factor.

By repeated backward substitution of the sequential budget constraint, and using the recursive definition of the state prices in equation (3.1), we recover the static budget constraint:

\[
\sum_{t \geq 1} \sum (z^t, \eta^t) \tilde{P}(z^t, \eta^t) \left[ \gamma Y(z^t) \eta_t - c(z^t, \eta^t) \right] + a_{t-1}(z_0) \geq 0,
\]

(3.2)

provided that interest rates are high enough. By the same token, repeated substitution delivers the following ‘static version’ of the measurability constraints for active traders in node \((z^t, \eta^t)\):

\[
\sum_{\tau \geq t} \sum (z^\tau, \eta^\tau) \tilde{P}(z^\tau, \eta^\tau) \left[ \gamma Y(z^\tau) \eta_\tau - c(z^\tau, \eta^\tau) \right] = -\tilde{P}(z^t, \eta^t) a_{t-1}(z^t, \eta^{t-1}).
\]

(3.3)

For passive traders, we simply replace \( a_{t-1}(z^t, \eta^{t-1}) \) on the right hand side by \( a_{t-1}(z^t, \eta^{t-1}) R^p(\varpi, z^t) \).

The extension to static solvency constraints is obvious:

\[
\sum_{\tau \geq t} \sum (z^\tau, \eta^\tau) \tilde{P}(z^\tau, \eta^\tau) \left[ \gamma Y(z^\tau) \eta_\tau - c(z^\tau, \eta^\tau) \right] \geq M(\eta^t, z^t).
\]

(3.4)

In the static optimization problem, each household chooses a consumption plan to maximize her expected utility subject to the static budget constraints in (3.2), the measurability constraints for her trading technology \( j \in \{z, bh, np\} \) in (3.3) and the solvency constraints in (3.4). A static equilibrium for this economy is defined in the standard way.

**Definition 3.1.** A static equilibrium consists of a consumption allocation \( \{c^t_{j-1}(z^t, \eta^t)\}, j \in \{z, bh, np\} \), wealth \( \{a^t_{j-1}(z^t, \eta^t)\} \), and a list of state prices \( P(z^t, \eta^t) \) such that: (i) given these
prices, a household’s asset and consumption choices maximize her expected utility subject to the static budget constraints in (3.2), the solvency constraints in (3.4) and the measurability constraints for her trading technology \( j \in \{z, bh, np\} \) in (3.3), and the goods markets clears in each node \( z^t \).

While every time-zero trading equilibrium has an equivalent sequential trading equilibrium, a sequential trading equilibrium only has an equivalent time-zero trading equilibrium if the present value of the aggregate endowment is finite under the constructed prices, or:

**Condition 3.1.** Interest rates are said to be high enough iff

\[
\sum_{t>0} \sum_{(z^t, \eta^t)} [Y(z^t)].\pi(z^t, \eta^t)P(z^t, \eta^t) < \infty
\]

This then implies that the present value of any individual’s initial endowment is also finite since the idiosyncratic shock is assumed to have finite support. In economies with sequential trading and borrowing constraints, it does not immediately follow that endowments are finitely valued in equilibrium (see Hellwig and Lorenzoni (2009)), because sequential budget and measurability constraints are implicitly backward-looking, while the time-zero trading economy has forward looking versions of these constraints.

**Proposition 3.1.** If condition (3.1) is satisfied, the sequential equilibrium allocations and prices can be implemented as an equilibrium of the static economy. Let the contingent bond positions \( \{a^t_{t-1}(z^t, \eta^t)\}, j \in \{z, bh, np\} \), the consumption allocation \( \{c^t_{t-1}(z^t, \eta^t)\}, j \in \{z, bh, np\} \), and the contingent bond prices \( \{q(z_{t+1}, z^t)\} \) be a sequential equilibrium. Then the state prices \( \{P(z^t, \eta^t)\} \) implied by \( \{q(z_{t+1}, z^t)\} \) and the consumption allocation \( \{c^t_{t-1}(z^t, \eta^t)\} \) constitute a static equilibrium.

Given these results, we can restate the household’s problem as one of choosing an entire consumption plan from a restricted budget set. The central result is a martingale condition for the stochastic multipliers.

### 3.1 Characterizing Equilibrium Allocations and Prices

In the static economy, markets open only once at time zero. The household chooses a consumption plan and a net wealth plan subject to a single budget constraint at time zero, as well as an infinite number of solvency constraints and measurability constraints. These measurability constraints act as direct restrictions on the household budget set. This optimization problem has a convex constraint set, as can easily be verified, because any convex combination of two allocations that satisfy the budget constraint, the solvency constraints and the measurability constraints, also satisfies these constraints. As a result of the convexity, if in addition we assume that the Markov process for \((z, \eta)\) satisfies the Feller condition and that the utility function is bounded, then (i) Lagrangian
multipliers exist for the budget constraint, the solvency and measurability constraints such that a saddle point can be found for an optimum of the static optimization problem (see proposition 2 in Mar cet and Marimon (1999)) and (ii) the saddle point problem is well-defined in its own right, i.e. it has a solution (see proposition 3 in Mar cet and Marimon (1999)). The boundedness of utility can be achieved by forcing the consumption shares (as a share of the aggregate endowment) to lie on a bounded set. This is what we do in the computational section (see separate appendix for details).

We start off by considering the active traders.

**Active Traders** Let \( \chi \) denote the multiplier on the present-value budget constraint, let \( \nu(z^t, \eta^t) \) denote the multiplier on the measurability constraint in node \((z^t, \eta^t)\), and, finally, let \( \varphi(z^t, \eta^t) \) denote the multiplier on the debt constraint. The saddle point problem of an active trader can be stated as:

\[
L = \min_{\{\chi, \nu, \varphi\}} \max_{\{c, a_{-1}\}} \sum_{t=1}^{\infty} \beta^t \sum_{z^t, \eta^t} u(c(z^t, \eta^t)) \pi(z^t, \eta^t) \\
+ \chi \left\{ \sum_{t \geq 1} \sum_{z^t, \eta^t} \bar{P}(z^t, \eta^t) \left[ \gamma Y(z^t) \eta_t - c(z^t, \eta^t) \right] + a_{-1}(z^0) \right\} \\
+ \sum_{t \geq 1} \sum_{z^t, \eta^t} \nu(z^t, \eta^t) \left\{ \sum_{\tau \geq t} \sum_{z^\tau, \eta^\tau} \bar{P}(z^\tau, \eta^\tau) \left[ \gamma Y(z^\tau) \eta_\tau - c(z^\tau, \eta^\tau) \right] + \bar{P}(z^t, \eta^t) a_{-1}(z^t, \eta^{t-1}) \right\} \\
+ \sum_{t \geq 1} \sum_{z^t, \eta^t} \varphi(z^t, \eta^t) \left\{ -M(z^t, \eta^t) \bar{P}(z^t, \eta^t) - \sum_{\tau \geq t} \sum_{z^\tau, \eta^\tau} \bar{P}(z^\tau, \eta^\tau) \left[ \gamma Y(z^\tau) \eta_\tau - c(z^\tau, \eta^\tau) \right] \right\}
\]

where \( \bar{P}(z^t, \eta^t) = \pi(z^t, \eta^t) P(z^t, \eta^t) \).

Following Mar cet and Marimon (1999), we can construct new weights for this Lagrangian as follows. First, we define the initial cumulative multiplier to be equal to the multiplier on the budget constraint: \( \zeta_0 = \chi \). Second, the multiplier evolves over time as follows for all \( t \geq 1 \):

\[
\zeta(z^t, \eta^t) = \zeta(z^{t-1}, \eta^{t-1}) + \nu(z^t, \eta^t) - \varphi(z^t, \eta^t).
\]

Substituting for these cumulative multipliers in the Lagrangian, we recover the following expression for the constraints component of the Lagrangian:

\[
\sum_{t \geq 1} \sum_{z^t, \eta^t} \bar{P}(z^t, \eta^t) \left\{ \zeta(z^t, \eta^t) \left( \gamma \eta^t Y(z^t) - c(z^t, \eta^t) \right) + \nu(z^t, \eta^t) a_{-1}(z^t, \eta^{t-1}) - \varphi(z^t, \eta^t) M(z^t, \eta^t) \right\} \\
+ \gamma \varphi(z^0).
\]
This is a standard convex programming problem – the constraint set is still convex, even with the measurability conditions and the solvency constraints. The first order conditions are necessary and sufficient. The first order condition for consumption implies that the cumulative multiplier measures the household’s discounted marginal utility relative to the state price $P(z^t)$:

$$\frac{\beta^t u'(c(z^t, \eta^t))}{P(z^t)} = \zeta(z^t, \eta^t).$$

(3.6)

This condition is common to all of our traders irrespective of their trading technology because differences in their trading technology do not affect the way in which $c(z^t, \eta^t)$ enters the objective function or the constraint portion of the Lagrangian. Hence, along the optimal consumption path, the marginal utility of households is proportional to their cumulative multiplier, regardless of their trading technology.

The first order condition with respect to net wealth $\hat{a}_t(z^{t+1}, \eta^t)$ is given by:

$$\sum_{\eta^{t+1} \succ \eta^t} \nu(z^{t+1}, \eta^{t+1}) P(z^{t+1}) = 0. \quad (3.7)$$

We refer to this as the martingale condition. This condition is specific to the trading technology. For the active trader, it implies that the average measurability multiplier across idiosyncratic states $\eta^{t+1}$ is zero since $P(z^{t+1})$ is independent of $\eta^{t+1}$. In each aggregate node $z^{t+1}$, the household’s marginal utility innovations not driven by the solvency constraints $(\nu_{t+1})$ have to be white noise. The trader has high marginal utility growth in low $\eta$ states and low marginal utility growth in high $\eta$ states, but these innovations to marginal utility growth average out to zero in each node $(z^t, z_{t+1})$. If the solvency constraints do bind, then the cumulative multipliers decrease on average:

$$E\{\zeta(z^{t+1}, \eta^{t+1})|z^{t+1}\} \leq \zeta(z^t, \eta^t),$$

which we obtained by substituting (3.5) into the first-order condition (3.7). Hence our recursive multipliers are a bounded super-martingale. The cumulative multiplier is a martingale if the solvency constraints do not bind for any $\eta^{t+1} \succ \eta^t$ given $z^{t+1}$.

The common characteristic for all active traders is that their marginal utility innovations are orthogonal to any aggregate variables, because we know that $E[\nu_{t+1}|z^{t+1}] = 0$ in each node $z^{t+1}$. Below, we explore the implications of this finding, but first, we show that buy-and-hold traders and non-participants satisfy the same martingale condition, but with respect to a different measure.
**Passive Traders**  For the passive investors, the constraints portion of the Lagrangian looks somewhat different:

\[ + \sum_{t \geq 1} \sum_{z^t, \eta^t} \tilde{P}(z^t, \eta^t) \left[ \zeta(z^t, \eta^t) \left( \gamma \eta^t Y(z^t) - c(z^t, \eta^t) \right) + \nu \left( z^t, \eta^t \right) a_{t-1}(z^t, \eta^{t-1}) R^p(\varpi, z^t) \right] \\
- \sum_{t \geq 1} \sum_{z^t, \eta^t} \tilde{P}(z^t, \eta^t) \left[ \varphi(z^t, \eta^t) M(z^t, \eta^t) \right] + \gamma \varpi(z^0). \]

The other components of the Lagrangian are unchanged. The first order condition with respect to \(a_{t-1}(z^t, \eta^{t-1})\) is given by:

\[ \sum_{z^{t+1} \succ z^t, \eta^{t+1} \succ \eta^t} \nu \left( z^{t+1}, \eta^{t+1} \right) R^p(\varpi, z^{t+1}) \pi(z^{t+1}, \eta^{t+1}) P(z^{t+1}) = 0. \quad (3.8) \]

The other conditions are identical. Using the recursive definition of the multipliers, the first order condition in (3.8) can be stated as:

\[ \zeta(z^t, \eta^t) \geq \sum_{z^{t+1} \succ z^t, \eta^{t+1} \succ \eta^t} \zeta(z^{t+1}, \eta^{t+1}) \tilde{\pi}(z^{t+1}, \eta^{t+1}|z^t, \eta^t), \quad (3.9) \]

where \(R(z^{t+1})\) is the return on the tradeable income claim and the twisted probabilities are defined as:

\[ \tilde{\pi}(z^{t+1}, \eta^{t+1}|z^t, \eta^t) = \frac{m(z^{t+1}|z^t) R^p(\varpi, z^{t+1})}{E \{m(z^{t+1}|z^t) R^p(\varpi, z^{t+1})|z^t\}} \pi(z^{t+1}, \eta^{t+1}|z^t, \eta^t), \]

So, the passive traders’ multipliers satisfy a martingale condition with respect to the these “risk-and-return-adjusted” probabilities, whenever the borrowing constraints do not bind. Moreover, when ever the debt constraints do bind, their multipliers are pushed downwards in order to satisfy the constraint. Relative to these twisted probabilities, the buy-and-hold traders’ multipliers are a super-martingale.

When \(z\) and \(\eta\) are independent, only the aggregate transition probabilities are twisted:

\[ \tilde{\pi}(z^{t+1}, \eta^{t+1}|z^t, \eta^t) = \tilde{\phi}(z^{t+1}|z^t) \varphi(\eta^{t+1}|\eta^t) \quad (3.10) \]

The same is true of the non-participant’s multipliers, however the twisting factor is different. In this case, \(R^p(0, z^{t+1})\) is the risk-free return \(R_f(z^t)\), which is measurable with respect to the aggregate history at \(t\). Hence, the first order condition with respect to \(\tilde{a}_t(z^{t+1}, \eta^{t+1})\) reduces to:

\[ \sum_{z^{t+1} \succ z^t, \eta^{t+1} \succ \eta^t} \nu \left( z^{t+1}, \eta^{t+1} \right) \pi(z^{t+1}, \eta^{t+1}) P(z^{t+1}) = 0. \quad (3.11) \]
This implies that non-participants’ multipliers have the super-martingale property:
\[
\zeta(z^t, \eta^t) E \{ m(z^{t+1} | z^t) | z^t \} \geq \sum_{z^{t+1} > z^t, \eta^{t+1} > \eta^t} \zeta(z^{t+1}, \eta^{t+1}) \tilde{\pi}(z^{t+1}, \eta^{t+1} | z^t, \eta^t)
\]  
with respect to the twisted probabilities
\[
\tilde{\pi}(z^{t+1}, \eta^{t+1} | z^t, \eta^t) = \frac{m(z^{t+1} | z^t)}{E \{ m(z^{t+1} | z^t) | z^t \}} \pi(z^{t+1}, \eta^{t+1} | z^t, \eta^t),
\]  
whenever the borrowing constraints do not bind.

**Euler equations** These martingale conditions enforce the Euler inequalities for the different traders:
(i) the non-participants:
\[
u'(c_t) \geq R_t \beta E_t \{ u'(c_{t+1}) \},
\]
(ii) the buy-and-hold traders:
\[
u'(c_t) \geq \beta E_t \{ R_{t+1} u'(c_{t+1}) \},
\]
(iii) the active traders:
\[
u'(c_t) \geq \beta E_t \left\{ u'(c_{t+1}) \frac{P(z^t)}{P(z^{t+1})} \right\}.
\]

These trading-technology-specific Euler equations follow directly from the martingale conditions, which depend on the trading technologies, and the first order condition for consumption, which do not. All households share the same first order condition for consumption, regardless of their trading technology. This implies that we can derive a consumption sharing rule and an aggregation result for prices.

### 3.2 Aggregate Multiplier

We can characterize equilibrium prices and allocations using the household’s multipliers and the aggregate multipliers.

**Proposition 3.2.** The household consumption share, for all traders is given by
\[
\frac{c(z^t, \eta^t)}{C(z^t)} = \frac{\zeta(z^t, \eta^t)^{\frac{-1}{\alpha}}}{h(z^t)}, \text{ where } h(z^t) = \sum_{\eta^t} \zeta(z^t, \eta^t)^{\frac{1}{\alpha}} \pi(\eta^t | z^t).
\]  

The SDF is given by the Breeden-Lucas SDF and a multiplicative adjustment:

\[
m(z^t+1|z^t) \equiv \beta \left( \frac{C(z^t+1)}{C(z^t)} \right)^{-\alpha} \left( \frac{h(z^t+1)}{h(z^t)} \right)^\alpha.
\]

(3.14)

The consumption sharing rule follows directly from the ratio of the first order conditions and the market clearing condition. Condition (3.6) implies that

\[
c(z^t, \eta^t) = u^t \left[ \frac{\zeta(z^t, \eta^t)P(z^t)}{\beta^t} \right] - \alpha \pi(\eta^t|z^t).
\]

In addition, the sum of individual consumptions aggregate up to aggregate consumption:

\[
C(z^t) = \sum_{\eta^t} c(z^t, \eta^t) \pi(\eta^t|z^t).
\]

This implies that the consumption share of the individual with history \((z^t, \eta^t)\) is

\[
\frac{c(z^t, \eta^t)}{C(z^t)} = \frac{\zeta(z^t, \eta^t)P(z^t)}{\beta^t} \sum_{\eta^t} \frac{1}{u^t-1} \left[ \frac{\zeta(z^t, \eta^t)P(z^t)}{\beta^t} \right] \pi(\eta^t|z^t).
\]

With CRRA preferences, this implies that the consumption share is given by

\[
\frac{c(z^t, \eta^t)}{C(z^t)} = \frac{\zeta(z^t, \eta^t)^{\frac{1}{\alpha}}}{h(z^t)} - \alpha \pi(\eta^t|z^t).
\]

Hence, the \(-1/\alpha\)th moment of the multipliers summarizes risk sharing within this economy. We refer to this moment of the multipliers simply as the aggregate multiplier. The equilibrium SDF is the standard Breeden-Lucas SDF times the growth rate of the aggregate multiplier. This aggregate multiplier reflects the aggregate shadow cost of the measurability and the borrowing constraints faced by households.

The expression for the SDF can be recovered directly by substituting for the consumption sharing rule in the household’s first order condition for consumption (3.6). This aggregation result extends the complete market result in Chien and Lustig (2006) to the case of incomplete markets and heterogeneous trading technologies. This proposition directly implies that an equilibrium for this class of incomplete market economies can be completely characterized by a process for these cumulative multipliers \(\{\zeta(\eta^t, z^t)\}\), and by the associated aggregate multiplier process \(\{h_t(z^t)\}\). Section 4 describes a method to solve for these multipliers.

We can use the consumption sharing rule and the martingale condition to highlight the main
features of the savings and investment behavior of active traders.

**Savings Investment Behavior** The active trader increases his consumption as a share of the aggregate endowment in aggregate states with low state prices, thus helping to clear the market.

**Corollary 3.1.** If the state price is low and \( h(z_{t+1})/h(z_t) \leq 1 \), the unconstrained active trader’s consumption share increases on average across \( \eta_{t+1} \) states in the next period. If the state price is high and \( h(z_{t+1})/h(z_t) > 1 \), her consumption share can increase or decrease.

Consider a hypothetical complete trader, who faces no measurability restrictions and has a constant multiplier in the absence of binding solvency constraints. This trader changes his consumption share at a rate \(-h(z_{t+1})/h(z_t)\) in each \( \eta_{t+1}, z_{t+1} \) state in the next period. This is an even more aggressive trading strategy; our active trader is more conservative because he still faces idiosyncratic risk.

The martingale condition for active traders puts tight restrictions on the joint distribution of returns and consumption growth. Using the SDF expression in (3.14), we can state the martingale condition as \( E_t[m_{t+1} \nu_{t+1}] = 0 \) for non-participants and active traders. This gives rise to the following expression for marginal utility growth of an unconstrained trader:

\[
E_t \left[ \frac{\zeta_{t+1}}{\zeta_t} \right] = 1 - E_t[m_{t+1}]^{-1} \text{cov}_t \left[ \frac{\zeta_{t+1}}{\zeta_t}, m_{t+1} \right] \tag{3.15}
\]

The covariance term drops out for active traders because \( E[\nu_{t+1}|z_{t+1}] = 0 \) in each node \( z_{t+1} \). This orthogonality condition is the hallmark of an “active trading” strategy. Active traders increase their consumption growth when state prices are lower than in the representative agent model, and they decrease consumption growth when state prices are higher than in the representative agent model, thus satisfying the orthogonality condition. However, this covariance term is non-zero for passive traders: their trading technology does not allow them to adjust consumption growth in different aggregate states of the world.

### 3.3 Aggregate Wealth in Different Segments

For the remainder of the paper, we focus on buy-and-hold investors can only trade the market portfolio, a claim to all of the diversifiable income. This implies that the buy-and-hold traders effectively hold a fixed portfolio of equity and bonds. The buy-and-hold trader invests a fraction \( \phi/(1 + \phi) \) in bonds and the remainder in equity. This portfolio is a natural benchmark, because this portfolio is the optimal one (and it is constant) in the case without non-participants in the IID economy. In subsection 6.3 we increase the equity holdings of the buy-and-hold investors.
By aggregating household wealth across all households in a trading segment \( j \), we can define the aggregate wealth for each group of traders \( j \in \{z, bh, np\} \):

\[
A^j(z^t) = \left[ \frac{h^j(z^t)}{h(z^t)} - \gamma \mu^j \right] C(z^t) + \sum_{z^{t+1}} \frac{\pi(z^{t+1})P(z^{t+1})}{\pi(z^t)P(z^t)} A^j(z^{t+1}),
\]

where we use the linearity of the pricing functional. Finally, total aggregate wealth equals the market portfolio:

\[
\sum_j A^j(z^t) = [\omega(z^t) + (1 - \gamma) Y(z^t)]
\]

This follows directly from market clearing. The measurability restrictions on the household wealth function in turn imply restrictions on the aggregate savings share of each trader group. These restrictions will help us understand the results in the quantitative section.

First, the buy-and-hold traders do not bear any of the residual aggregate risk, (in terms of their savings share) created by non-participants.

**Proposition 3.3.** Conditional on \( z^{t-1} \), the aggregate savings share \( \frac{A^{bh}(z^t)}{[\omega(z^t) + (1 - \gamma) Y(z^t)]} \) of buy-and-hold traders cannot depend on \( z_t \).

Since the measurability constraints are satisfied for the individual household’s savings function, they also need to be satisfied for the aggregate savings function. So by the LLN:

\[
\frac{A^{bh}(z^t, z_{t+1})}{[(1 - \gamma) Y(z^t, z_t) + \omega(z^t, z_t)]} = \frac{A^{bh}(z^t, \tilde{z}_{t+1})}{[(1 - \gamma) Y(z^t, \tilde{z}_{t+1}) + \omega(z^t, \tilde{z}_{t+1})]}
\]

where we have used the fact that the denominator is measurable w.r.t. \( z^t \). The household measurability condition implies that the aggregate savings of the buy-and-hold traders be proportional to the diversifiable income claim in all the aggregate states \( z_{t+1} \). This is not surprising, since the buy-and-hold traders hold the market portfolio. Note that constant aggregate consumption shares \( \frac{h^{bh}(z^t)}{h(z^t)} \) for the buy-and-hold traders would trivially satisfy this aggregate measurability constraint. Since any other consumption sequence would yield less in total expected utility, this implies that the aggregate consumption share of the buy-and-hold traders is constant.

**Corrollary 3.2.** Conditional on \( z^{t-1} \), the aggregate consumption share of the buy-and-hold traders \( \frac{h^{bh}(z^t)}{h(z^t)} \) cannot depend on \( z_t \).

This is what we find is the equilibrium outcome in the calibrated version of the model.

Second, the non-participants create residual aggregate risk.

**Proposition 3.4.** Conditional on \( z^{t-1} \), the aggregate savings share of non-participants \( \frac{A^{np}(z^t)}{[\omega(z^t) + (1 - \gamma) Y(z^t)]} \) is inversely proportional to the aggregate endowment growth rate.
This follows directly from the measurability condition of the non-participant households, which implies that their individual, and hence their aggregate, saving level cannot depend upon $z_{t+1}$.

Finally, since the buy-and-hold traders have (conditionally) constant savings shares, and the non-participant traders have counter-cyclical savings shares, regardless of the $\{h\}$ process, there cannot be an equilibrium without active traders. The market simply cannot be cleared without active traders, if there are non-participants.

The next section derives a recursive set of updating rules for the aggregate multipliers.

4 Computation

This section describes a recursive, computational method that exploits the martingale conditions for different traders and the consumption sharing rule to compute the equilibrium allocations and prices.

4.1 System of Equations

To allow us to compute equilibrium allocations and prices for a calibrated version of this economy, we recast our optimality conditions in recursive form. Making use of the consumption sharing rule, we can express the household’s present discounted value of future consumption minus future labor income or wealth as a function of the individual’s multiplier:

$$a(\zeta(z_t, \eta_t); z_t, \eta_t) = \left[ \frac{\zeta(z_t, \eta_t)}{h(z_t)} - \gamma \eta_t \right] C(z_t)$$

$$+ \sum_{z_{t+1}, \eta_{t+1}} \frac{\pi(z_{t+1}, \eta_{t+1})P(z_{t+1})}{\pi(z_t, \eta_t)P(z_t)} a(\zeta(z_{t+1}, \eta_{t+1}); z_{t+1}, \eta_{t+1}).$$

We refer to this as the recursive savings equation. This recursive expression holds for all of our different asset traders.

The Kuhn-Tucker condition on the borrowing constraint reads as:

$$\varphi(\eta_{t+1}, z_{t+1}) \left[ -a(\zeta(z_{t+1}, \eta_{t+1}); z_{t+1}, \eta_{t+1}) + \frac{M(z_{t+1}, \eta_{t+1})}{\pi(z_{t+1}, \eta_{t+1})} \right] = 0.$$ (4.2)

This condition is common to all traders, regardless of the trading technology. However, the measurability and optimality conditions depend upon the trading technology.

Active Traders  We start with the case of active traders. Let $a^z(\cdot)$ denote the active trader’s wealth. The measurability constraint requires that the discounted value of the future surpluses be
equal for each future $\eta^{t+1}$, or

$$a^z(\zeta(z^{t+1}, \eta^{t+1}); z^{t+1}, \eta^{t+1}) = a^z(\zeta(z^{t+1}, \tilde{\eta}^{t+1}); z^{t+1}, \tilde{\eta}^{t+1})$$

for all $\eta^{t+1}, \tilde{\eta}^{t+1}$ and $z^{t+1}$.

This implies the following Kuhn-Tucker condition for the measurability constraints:

$$[a^z(\zeta(z^{t+1}, \eta^{t+1}); z^{t+1}, \eta^{t+1}) - a^z(\zeta(z^{t+1}, \tilde{\eta}^{t+1}); z^{t+1}, \tilde{\eta}^{t+1})] \nu(\eta^{t+1}, z^{t+1}) = 0$$

for all $\eta^{t+1}, \tilde{\eta}^{t+1}$ and $z^{t+1}$. Conditions (4.2-4.3) and the martingale condition (see eq. (3.7)), reproduced here,

$$\sum_{\eta^{t+1}>\eta^t} \nu \left( z^{t+1}, \eta^{t+1} \right) \pi(z^{t+1}, \eta^{t+1}) P(z^{t+1}) = 0$$

determine the multiplier updating function:

$$T^z(z^{t+1}, \eta^{t+1}|z^t, \eta^t)(\zeta(z^t, \eta^t)) = \zeta(z^{t+1}, \eta^{t+1}).$$

$T^z$ is determined by solving a simple set of simultaneous equations. Let $#$ denote the cardinality of a set. Using the martingale condition, note that in each node $z_{t+1}$, we have $#Y - 1$ measurability equations to be solved for $#Y - 1$ multipliers $\nu(\eta^t, \eta_{t+1}, z^{t+1})$, one for each $\eta_{t+1}$. In addition, in each node $z_{t+1}$, we have $#Y - 1$ Kuhn-Tucker conditions to be solved for $#Y - 1$ multipliers $\varphi(\eta^t, \eta_{t+1}, z^{t+1})$, one for each $\eta_{t+1}$. Finally, the law of motion for the cumulative multiplier $\zeta$ is given in (3.5).

**Passive Traders** For passive traders, which includes both the buy-and-hold investors and the nonparticipants as special cases, the measurability condition is given by:

$$\frac{a^j(\zeta(z^{t+1}, \eta^{t+1}); z^{t+1}, \eta^{t+1})}{R^p(z^t, \tilde{z}_{t+1})} = \frac{a^j(\zeta(z^t, \tilde{z}_{t+1}, \eta^t, \tilde{\eta}_{t+1}); z^t, \tilde{z}_{t+1}, \eta^t, \tilde{\eta}_{t+1})}{R^p(z^t, \tilde{z}_{t+1})}, j \in \{bh, np\}$$

for all $\eta^{t+1}, \eta^t, \tilde{\eta}_{t+1}, z^{t+1}$ and $z^t, \tilde{z}_{t+1}$, the martingale condition becomes:

$$\sum_{z^{t+1}>z^t, \eta^{t+1}>\eta^t} \nu \left( z^{t+1}, \eta^{t+1} \right) R^p(z^t, \tilde{z}_{t+1}) \pi(z^{t+1}, \eta^{t+1}) P(z^{t+1}) = 0.$$  \hspace{1cm} (4.5)

The updating functions for the passive traders,

$$T^j(z^{t+1}, \eta^{t+1}|z^t, \eta^t)(\zeta(z^t, \eta^t)), j \in \{bh, np\}$$

are the solution to conditions (4.2), the Kuhn-Tucker condition associated with the measurability condition (4.4) and their martingale condition (4.5). For the buy-and-hold traders, the appropriate
Definition 4.1. The updating function $T^j(\cdot), j \in \{z, bh, np\}$ is a solution to a system of equations defined by:

1. the **measurability** conditions using the recursive expression for $a^j$

2. the **martingale** conditions

3. the **borrowing constraint** using recursive expression for $a^j$

Finally, these updating functions for each of the trading technologies $T^j(\cdot), j \in \{z, bh, np\}$ determine the law of motion for the aggregate multiplier:

$$h(z^{t+1}) = \sum_{j \in T^j} \int \sum_{\eta^{t+1} > \eta^t} \left\{ T^j(z^{t+1}, \eta^{t+1}|z^t, \eta^t)(\zeta(z^t, \eta^t)) \right\} \frac{\pi(\eta^{t+1}, z^{t+1}|\eta^t, z^t)}{\pi(z^{t+1}|z^t)} d\Phi_j,$$

where $\Phi_j$ is the joint distribution of multipliers and endowments and $j \in \{z, bh, np\}$.

These aggregate multiplier dynamics govern the dynamics of the SDF, and hence of risk premia and asset prices. Clearly, this defines an aggregate multiplier updating operator $\{h^t(z^t)\} = T^h\{h^0(z^t)\}$ that maps the initial multiplier function $\{h_t(z^t)\}$ into a new aggregate multiplier function. We are looking for a fixed point of this operator. We conclude this section by explaining the computational algorithm in detail.

### 4.2 Algorithm

In general, the growth rate of the aggregate multiplier process depends on the entire history. Of course, in an infinite horizon economy, we cannot record the entire aggregate history of shocks in the state space. To actually compute equilibria in a calibrated version of this economy, we propose an algorithm that only uses the last $n$ shocks, following Veracrierto (1998), and we use $s$ to denote a truncated aggregate history in $Z^n$. We define $\widehat{g}(s, s')$ as the forecast of the aggregate multiplier growth rate $[h'(z^{t+1})/h(z^t)]$, conditional on the last $n$ elements of $z^{t+1}$ equaling $s'$ and the last $n$ elements of $z^t$ equaling $s$.

**Definition 4.2.** The algorithm we apply is:

1. **conjecture a function** $\widehat{g}_0(s, s') = 1$.

2. **solve for the equilibrium updating functions** $T^j_0(s', \eta'|s, \eta)(\zeta)$ for all trader groups $j \in \{z, bh, np\}$. This step is described in detail below.
3. By simulating for a panel of \( N \) households for \( T \) time periods, we compute a new aggregate weight forecasting function \( \hat{g}_1(s, s') \).

4. We continue iterating until \( \hat{g}_k(s, s') \) converges.

In our approximation, we allocate consumption to households with a version of the consumption sharing rule that uses our forecast of the aggregate multiplier \( \hat{g}(s, s') \) in each aggregate node \( s \), \( \frac{1}{\zeta} / \hat{g}(s, s') \). Prices are set using the forecast as well: \( m(s', s) \equiv \beta e^{-\alpha z'} \hat{g}(s, s')^\alpha \). Of course, this implies that actually allocated aggregate consumption \( C^a \) differs from actual aggregate consumption \( C \):

\[
C(z_t^{t+1}) = \frac{g(z_t^{t+1})}{\hat{g}(s, s')} Y(z_t^{t+1}),
\]

where \( g(z_t^{t+1}) \) is the actual growth rate of the aggregate multiplier in that aggregate node \( z_t^{t+1} \). This equation simply follows from aggregating our consumption sharing rule across all households. When the forecast \( \hat{g}(s, s') \) deviates from the realized growth rate \( g(z_t^{t+1}) \), this causes a gap between total allocated consumption and the aggregate endowment. Hence, the percentage forecast errors are really allocation errors. However, the household’s Euler equation holds exactly in each node, given that we have set the prices and allocated consumption in each node on the basis of the forecasted aggregate multiplier, not the realized one.

We use a finite history of length \( n = 6 \) of the aggregate shocks to (reasonably) accurately compute the equilibrium. The variable \( n \) determines the set of aggregate finite histories \( S(n) \) that we are keeping track of, and \( s \in S(n) \) denotes a generic member. The household’s state variables are given by her multiplier \( \zeta \), the finite aggregate history \( s \), and her individual shock \( \eta \). A detailed description of the implementation of this algorithm is available in the separate appendix. Next, we solve a calibrated version of this economy numerically, to examine the quantitative importance of heterogeneous trading opportunities for asset prices.

5. Quantitative Results in Benchmark Model

This section evaluates a calibrated version of the model. The benchmark model has no aggregate consumption growth predictability (IID economy). Hence, all of the dynamics are generated by the heterogeneity of trading technologies. We start with the calibration of the model in subsection 5.1, while subsection 5.2 discusses the approximation in detail. Subsection 5.3 shows that the model with heterogeneous trading opportunities manages to reconcile the low volatility of the risk free rate with the large and counter-cyclical volatility of the stochastic discount factor. Finally,

\[\textit{The number of elements of } S(n) \textit{ is given by } n^{\#Z}, \text{ where } \#Z \textit{ is the number of aggregate states (2).}\]

\[\textit{Besides her multiplier, there are } n^{\#Z} \times \#N \textit{ states for the individual.}\]
subsection 5.4 gives us detailed account of how the heterogeneity in trading technologies affect the household’s consumption and portfolio.

5.1 Calibration

The model is calibrated to annual data. We choose a coefficient of relative risk aversion $\alpha$ of five and a time discount factor $\beta$ of .95. These preference parameters allow us to match the collateralizable wealth to income ratio in the data when the tradeable or collateralizable income share $1 - \gamma$ is 10%, as discussed below. Non-diversifiable income includes both labor income and entrepreneurial income, among other forms. The average ratio of household wealth to aggregate income in the US is 4.30 between 1950 and 2005. The wealth measure is total net wealth of households and non-profit organizations (Flow of Funds Tables). We choose a collateralizable income ratio $\alpha$ of 10%.

The implied ratio of wealth to consumption is higher (6.3) in the model’s benchmark calibration, mainly because of the low risk-free rate. The households face exogenous limits on their net asset positions. The value of the household’s net assets must always be greater than $-\psi$ times the value of their non-diversifiable income, where $\psi \in (0, 1)$. We define the lower bound $M(\eta_t^t, z_t^t)$ as follows:

$$M(\eta_t^t, z_t^t) = -\psi \sum_{\tau \geq t} \sum_{\{z^\tau \geq z_t^t, \eta^\tau \geq \eta_t^t\}} \gamma Y(z^\tau) \eta_t \frac{\pi(z^\tau, \eta_t^\tau) P(z^\tau, \eta_t^\tau)}{\pi(z_t^t, \eta_t^t) P(z_t^t, \eta_t^t)}$$

(5.1)

We set the solvency constraint equal to zero: $M = 0$.

In our benchmark model, 70% of households only trade the riskless asset. The remaining 30% is split between buy-and-hold investors and active traders. This market segmentation was chosen to match the key moments of asset prices in the post-war period. In section 6 we increase the participation rate to 50%. This number is more appropriate for the last two decades of the US experience. To check the plausibility of this calibration, we show that this segmentation allows for a close match of the recent asset share distribution and a better match of the recent wealth distribution in the US. This is an out-of-sample test of our calibration strategy.

In the benchmark calibration, there is no predictability in aggregate consumption growth, as in Campbell and Cochrane (1999) –we impose

$$\phi(z_{t+1}|z_t) = \phi(z_{t+1}).$$

(5.2)

We refer to this as the IID economy. This is a natural benchmark case because all of the equilibrium dynamics in risk premia flow from the binding borrowing and measurability constraints, not from the dynamics of the aggregate consumption growth process itself. The other moments for aggregate consumption growth are taken from Mehra and Prescott (1985). The average consumption growth rate is 1.8%. The standard deviation is 3.15%. Recessions are less frequent: 27% of realizations
are low aggregate consumption growth states.

In addition, we impose independence of the idiosyncratic risk from aggregate shocks on the labor income process – the following condition holds:

\[ \pi(\eta_{t+1}, z_{t+1} | \eta_t, z_t) = \varphi(\eta_{t+1} | \eta_t) \phi(z_{t+1} | z_t). \]  

\hspace{1cm} (5.3)

By shutting down counter-cyclical cross-sectional variance (CCV) of labor income shocks, we want to focus on the effects of concentrating aggregate risk among a small section of households, as opposed to concentrating income risk in recessions. The Markov process for \( \log \eta(y, z) \) is taken from Storesletten, Telmer, and Yaron (2007) (see page 28). The standard deviation is .60, and the autocorrelation is 0.89. We use a 4-state discretization. The elements of the process for \( \log \eta \) are \{0.38, 1.61\}.

This section discusses the asset pricing implications of heterogeneous trading opportunities in the IID version of our economy. We use the IID economy as a laboratory for understanding the interaction between active and passive traders and its effect on asset prices. This interaction generates counter-cyclical state price volatility without risk-free rate volatility, unlike other heterogeneous agent models (see e.g. Chien and Lustig (2006), Alvarez and Jermann (2001), and Guvenen (2003)). The IID economy provides a natural benchmark because all investors hold the market and the risk premium is the Breeden-Lucas one if there are no non-participants. In subsection 6.4, we activate the CCV mechanism and we allow for predictability in aggregate consumption growth.

We consider two cases in the HTT (heterogeneous trading technology) economy. In the first 2 cases (reported in columns (2) and (3)), only a fraction of the market participants are active traders. In the LP (Limited Participation) economy (reported in columns (4) and (5)), all participants are active traders. Case (1) is the benchmark. The active traders make up 10% of the population. The remaining 90% is split between 20% buy-and-hold traders and 70% non-participants. We choose a low participation rate because the model’s market segmentation was calibrated to match the moments of asset prices for the entire post-war period. Case (2) considers the case with only 50% non-participants, while the active traders still make up only 10% of the population. This case offers a better description of market segmentation in the last two decades. As an out-of-sample check of the model’s market segmentation, we compare the implications of these choices for the wealth distribution and the asset class share distribution against the data in subsection 6.1. Finally, Case (3) and (4) (reported in columns (4) and (5)) consider what happens when all participants are active traders. This is the standard case considered in the literature on limited participation. The difference between Case (1) and (3) (as well as the difference between Case (2) and Case (4)) show the effect of the heterogeneity in trading technologies. Finally, the last column reports the moments in the data.
5.2 Approximation

To assess the accuracy of the approximation method, we report the highest standard deviation of the actual simulated realizations of log $g$, conditioning on the truncated history $s$ of length 6, in the last row of Table 1. If our method were completely accurate, this statistic would be zero because the actual realizations would not vary in any truncated history $s$. In that case, the planner makes no allocation errors. In the IID economy, this coefficient varies between .26% and .50%. So, the forecasting errors are small. In the worst case, a 2 standard deviation error is an allocation error of less than 1% (see equation (4.2) for a definition of the allocation error). The truncated aggregate history explains most of the variation in log $g$. The quality of the approximation does not depend on the composition of the passive trader pool.

Moments of Multiplier Distribution A natural question is whether our computational procedure would converge if we used moments of the wealth distribution to forecast the pricing kernel for each aggregate transition $(z', z)$ instead of truncated aggregate histories. Table 2 addresses this question. The left panel reports results for the IID economy, the right panel reports results for the non-IID economy. We consider Case (1), our benchmark case with 70% nonparticipants, and Case (2), the case with only 50% non-participants. We run forecasting regressions on samples of 10,000 observations generated by simulating the version of our model solved using our approximation with truncated aggregate histories, and computing the realized aggregate weight growth $g$. We have just shown that our method produces small approximation errors. Following Krusell and Smith (1997), the table reports for each aggregate transition $(z, z')$ the $R^2$ in a linear time-series regression of the realized aggregate weight growth log $g(z', z)$ on moments of the wealth distribution:

$$g(z', z')(t + 1) = \alpha(z', z) + \beta(z'z, )M(t) + u(t + 1),$$

where $M(t)$ is the vector of moments of the cross-sectional wealth distribution. In the left panel of Table 2, we report the results for the IID economy. We consider various cases for $M$. In the first two cases, we use only the moments of the entire multiplier distribution. In the last three cases, we distinguish between the moments of the multiplier distribution for active and passive traders. We use $M_i(W_T)$ to denote a vector with the first $i$ moments of the wealth distribution, $M_i(W_A)$ for active traders and $M_i(W_P)$ for passive traders.

The first two moments of the entire multiplier distribution (reported in column (1)) for all households account for less than 60% of the variation in $g$, and, in the worst case, only 37%. The first three moments (reported in column (2)) still only account for 39% of the variation in the worst case. Introducing moments for active traders separately in the forecasting regression improves the overall performance substantially and the worst-case $R^2$ to 50% (see column (4) and (5)). However, this comes at the cost of introducing 5 continuous state variables. Moreover, this
is still well below the numbers reported by Krusell and Smith (1997).

As a benchmark, column (6) in each panel reports the $R^2$ implied by our forecasting method. These vary between 95 % and 88%. Our method produces high $R^2$ in states with a lot of variation in the aggregate multiplier shocks $g$. The method delivers an $R^2$ of 93 % in the high to low transitions, with $\text{std}(\log g)$ of 4.8 %. The $R^2$ is only 88 % in the high to high case, with a standard deviation $\text{std}(\log g)$ of only 2.80 %; the shocks to the SDF are small when the economy moves between expansions.

Reducing the non-participant pool to 50 % improves the forecasting performance of the moment method. These results are reported in the second panel (Case (2)). The worst $R^2$ is still about 47% if we reduce the size of the non-participant pool to 50 %. Our method explains more than 93 % of the variation in all cases. Of course, in the limit, with 0 % non-participants, the distinction between buy-and-hold and active traders is moot, and the growth rate of the aggregate multiplier is constant in equilibrium. In this case, the $R^2$ of the linear regression is 100 % even without any moments. However, the presence of non-participants destroys the quasi-aggregation result in Krusell and Smith (1997).

### 5.3 Asset Pricing Results

The asset pricing statistics were generated by drawing 10,000 realizations from the model, simulated with 3000 agents. The left panel of Table 1 reports the asset pricing results in our baseline IID experiment; the right panel reports the result for the Non-IID economy with autocorrelation in aggregate consumption growth shocks and CCV in labor income risk.

Equity in our model is simply a leveraged claim to diversifiable income. In the Flow of Funds, the ratio of corporate debt-to-net worth is around 0.65, suggesting a leverage parameter $\psi$ of 2. However, Cecchetti, Lam, and Mark (1990) report that the standard deviation of the growth rate of dividends is at least 3.6 times that of aggregate consumption, suggesting that the appropriate leverage level is over 3. Following Abel (1999) and Bansal and Yaron (2004) , we choose to set the leverage parameter $\psi$ to 3. The returns on this security are denoted $R_{tc}$.

As a benchmark, the first column in the table also reports the corresponding numbers for the RA (representative agent) economy. This case is relevant, because, in the IID Economy, all of the moments of risk premia reported in column (1) are identical in the HTT economy without non-participants, regardless of the composition of the pool of participants.

As long as all households can trade a claim to diversifiable income, the lack of consumption smoothing has no bearing on risk premia, and its only effect is to lower the equilibrium risk-free rate (not reported in the table). The equilibrium distribution of the household multipliers (and hence the second component of the SDF $h(z^{t+1})/h(z^t)$ in equation (3.14)) does not depend on the realization of the aggregate shocks. To prove this result, we show that the multiplier updating
functions $T^a$ do not depend on the aggregate history $z^t$, provided that (i) the aggregate shocks are i.i.d and (ii) the idiosyncratic shocks are independent of the aggregate shocks (ie conditions (5.2) and (5.3) are satisfied). The proof is in the separate appendix. In this case, the risk-free rate is lower than in the representative agent economy, but the risk premia are identical. Hence, we need non-participants to get non-trivial asset pricing effects of heterogeneity in trading technologies. In the IID economy without non-participants, the composition of the other trader segments has no effect on the equity premium; the Breeden-Lucas (RA) risk premium obtains and all traders hold the market portfolio. However, as soon as there is a positive fraction of non-participants, this irrelevance result disappears, and the active traders increase their exposure to market risk.

In the RA economy, the maximum Sharpe ratio is .19 and the equity risk premium $(E[R_{lc} - R_f])$ is 2.3%. The conditional market price of risk $[\sigma_t[m]/E_t[m]]$ is constant, because the aggregate consumption growth shocks are i.i.d. Hence, the risk premia are constant as well. Finally, the risk-free rate in the RA economy is 12% and it is also constant. As a result, there is no risk in bond returns $(E[R_b - R_f] = 0)$. Hence, all of the dynamics reported below are generated by the heterogeneity in trading technologies.

In the HTT economy, the interaction between active and passive traders generates volatile state prices and a stable risk-free rate. In case (1) of the HTT economy, the maximum Sharpe ratio $(\sigma[m]/E[m])$, is .44. The risk premium on equity is 6.7% $(E[R_{lc} - R_f])$, while the standard deviation of returns $(\sigma [R_{lc} - R_f])$ is 15.2%. This is still well below the average realized excess return in post-war US data of 7.5%. The risk-free rate $R_f$ is low (1.73%) and essentially constant. The standard deviation of the risk-free rate is .06%. There is also substantial time variation in expected excess returns; the standard deviation of the conditional market price of risk $Std [\sigma_t[m]/E_t[m]]$ is 3.3%, comparable to that in Campbell and Cochrane (1999) ’s model. The conditional market price of risk varies between .35 and .6. Variation in $\gamma$, the tradeable income share, only affects the average risk-free rate, but it does not affect the risk premia in this economy.

If we increase $\gamma$ to .20, the equity premium drops 3 basis points and the maximum SR drops from .45 to .44. However, the risk-free rate increases to 2.94 percent per annum (not shown in the table).

To illustrate the time variation in risk prices, figure 1 plots a simulated path of 100 years for the $\{h'/h\}$ shocks to the aggregate multiplier process, the conditional risk premium on equity and the conditional market price of risk in the bottom panel. The shaded areas in the graph indicate low aggregate consumption growth states. As is clear from the top panel in Figure 1 $[h'/h]$ is large in recessions -low aggregate consumption growth states- to induce the active traders to consume less in that state of the world, because the passive traders consume “too much” in those states. Similarly, $[h'/h]$ needs to be small in high aggregate consumption growth states, to induce the active traders to consume more in those states. The volatility in state prices induces

---

7This result is an extension of Krueger and Lustig (2006)’s result to the case of segmented markets.
the small segment of active traders to reallocate consumption across aggregate states and absorb the residual aggregate risk from the non-participants. The middle panel plots the expected excess return on equity $E[R_{tc} - R_f]$. Clearly, the IID economy produces counter-cyclical variation in the risk premium. The underlying mechanism is shown the Net Wealth panel. The interaction between active and passive traders generates counter-cyclical variation in the conditional market price of risk $[\sigma_t[m]/E_t[m]]$. In high $[h'/h]$ states, active traders realize low portfolio returns. The wealth of active traders decreases as a fraction of total wealth. This means, that in order to clear the market, the future $[h'/h]$ -shocks need to be larger (in absolute value), and this in turn increases the conditional volatility of the stochastic discount factor. As a result, the conditional market price of risk $[\sigma_t[m]/E_t[m]]$ increases after each low aggregate consumption growth realization. The driving force behind the time variation is the time-varying exposure of active traders to equity risk. We explore this in the next subsection.

[Figure 1 about here.]

5.4 Household Portfolio Choice and Consumption

The welfare costs of being stuck with an inferior trading technology are large. The costs are reported in percentage of lifetime consumption on the bottom of Table 1. They vary from 8% for the buy-and-hold investor to 14% for non-participants. This is not surprising when we consider the impact on household consumption and wealth. The reason for the heterogeneity in portfolio choice is not only the heterogeneity in trading technologies, but also the presence of non-participants.

In the case without non-participants, all households, complete, active and buy-and-hold traders would choose the same market portfolio: 25% equity and 75% bonds, and the welfare costs of being a buy-and-hold investor are zero. However, in the case of non-participation, the fraction active traders invest in equity varies over time and across traders. On average, the equity share is 83% for the active trader. These fractions are highly volatile as well. The standard deviation is 23% for the active trader. Not surprisingly, the heterogeneity in portfolio choice shows up in portfolio returns. The second panel in Table 1 reports the average portfolio returns realized by all traders in a segment and the average wealth they accumulate. We take case (1) as our benchmark. We start with the active investors. Their investment strategy delivers an average excess return on their portfolio of 5.60% ($E[R_{aw} - R_f]$) or roughly 110 basis points less than the equity premium. The buy-and-hold investor earns excess returns of around 1.6% while the non-participants realize zero excess returns. As a result, these investors do not manage to accumulate wealth. Because of his superior trading technology, the active traders accumulates 2.75 times the average wealth level ($E[W_t/W]$), while the diversified trader is right at the average. Non-participants fail to accumulate wealth; on average, their holdings amount to only 76% of the average. This will severely limit the amount of self-insurance these non-participant households can achieve. On average, active trader
accumulates 3.61 times more wealth than the non-participant. Because the active trader invests a large fraction of his wealth in the risky asset, his wealth share is highly volatile. The coefficient of variation for the active trader’s wealth share is 45%. However, most of this reflects aggregate rather than idiosyncratic risk. On the other hand, these coefficients of variation for the passive traders are higher, but that reflects mostly idiosyncratic risk.

On average, the active trader invests 82% in equity, but the fraction is highly volatile (23%). Figure 1 also plots the active investor’s net wealth and his equity share (share of total portfolio invested in leveraged consumption claim’s). The equity share varies substantially over time, between 50 and 150%. Their equity exposure tracks the variation in the conditional market price of risk and the equity premium perfectly. Since the active traders are highly leveraged, their share of total wealth (see top panel) declines substantially after a low aggregate shock, and their “market share” declines. As a result, the conditional volatility of the aggregate multiplier shocks increases; larger shocks are needed to get the active traders to clear the markets. In response to the increase in the conditional market price of risk, the active traders increase their leverage.

This heterogeneity in portfolio choice shows up in household consumption and aggregate consumption for each trader segment as well. We report moments for household consumption as well as for average consumption aggregated across all households in a trader segment. The standard deviation of household consumption share growth can be ranked according to the trading technology, from 7.8% for the active traders to 12% for the non-participants. The standard self-insurance mechanism breaks down for non-participants and buy-and-hold traders; they fail to accumulate enough assets to self-insure. However, the standard deviation of the growth rate of the cross-sectional average of household consumption in a trader segment actually is highest for more sophisticated traders: \( \sigma[\Delta \log(\bar{C}_c)] \) is 3.9 %, the same number is only 1% for non-participants and .3 % for buy-and-hold traders. We pointed out that constant aggregate consumption shares for the buy-and-hold traders trivially satisfy the aggregate measurability constraint. This turns out to be roughly what we find is the equilibrium outcome.

Financially sophisticated households load up on aggregate consumption risk, but they are less exposed to idiosyncratic consumption risk. This is broadly in line with the data. Malloy, Moskowitz, and Vissing-Jorgensen (2007) find that the average consumption growth rate for stockholders is between 1.4 and two times as volatile as that of non-stock holders. They also find that aggregate stockholder consumption growth for the wealthiest segment (upper third) is up to 3 times as sensitive to aggregate consumption growth shocks as that of non-stock holders. The same number for all stockholders is only 1.4. We report the beta of group consumption growth w.r.t. aggregate consumption growth \( \beta[\Delta \log(C_i), \Delta \log(C_a)] \) in the lower panel of Table 3. In our model, this number is 2.07 for the active traders. For buy-and-hold traders, the beta is one, as predicted by the theory.
Next, we look at the correlation with stock returns in the bottom panel. As a useful benchmark, recall the case without non-participants. Household consumption shares do not depend on aggregate shocks $z^t$, regardless of their trading technology, and the correlation of consumption share growth with returns is zero $\rho [R_s, (\Delta \log(c_i))] = 0$ for all households. In the HTT economy, because of the presence of non-participants, the correlation of consumption share growth with stock returns is highest for active traders (.48), and decreases to .58 for active traders and 0 for buy-and-hold traders. The overall correlation for the participants $\rho [R_s, (\Delta \log(c_p))]$ is only about .16.

Of course, the active and complete traders absorb the residual of aggregate risk created by the passive traders. The aggregate consumption share growth of this trader segment ($\hat{C}^j(z^t) = h^j(z^t)/h(z^t)$) has a correlation of .95 with stock returns. The same correlation for buy-and-hold investors is -.08, while the correlation for non-participants is -.9.

# 6 Sensitivity Analysis

We conduct a series of additional experiments to help understand the effects of heterogeneity in trading technologies on asset prices. In the first experiment in subsection 6.1, we increase the rate of participation to match the current participation rate. The equity premium drops by 75 basis points as a result. We look at the wealth and asset share distribution implications of this calibration and compare these to current data from the Survey of Consumer Finances. In the second experiment in subsection 6.2, we replace the passive stockholders with active stockholders to decompose the results into a limited participation effect and a HTT effect. In the third experiment, we change the composition of the passive trader segment (subsection 6.3) to show that only the average equity holdings of the passive traders matters, not the actual composition. Finally, we relax the i.i.d. assumption for aggregate consumption growth in subsection 6.4.

## 6.1 Increased Participation

Case (2) (reported in column (3)) reports the effect on asset prices in the HTT economy when participation increases to 50 %. This is also closer to the actual participation rate in the US economy in the last decade. Active traders still make up 10 % of the population. The market price of risk drops from .44 to .40 and the equity premium drops by 75 basis points to 5.97 %. Hence, our model predicts a substantial decrease in the risk premium as a result of recent increases in participation, consistent with the evidence reported in Fama and French (2002) and Jagannathan, McGrattan, and Scherbina (2000). However, the equity premium is still almost 300 basis points larger than in the representative agent economy. In addition, the increased participation reduces the volatility of the market price of risk from 3.9 to 3.3%.
Implications for the Wealth Distribution  Table 4 compares the wealth distribution implications of this version of the calibrated model to wealth data from the 2001 Survey of Consumer Finances. We introduce permanent income differences to match the joint income distribution and wealth distribution in the data, while keeping the fraction of human wealth in each trader segment constant. This way, the asset pricing implications of the model are preserved because of the homogeneity that is built into the model. In the twisted calibration, the active traders make up 5% of the population and hold 10% of human wealth. The buy-and-hold traders hold 35% of human wealth but make up 40% of the population. Finally, the non-participants hold 50% of wealth but make up 65% of the population. The first two columns display the model’s income distribution vs that in the data at different percentiles of the wealth distribution. We obtain a close match of the income distribution in the data.

We consider two benchmark models. The Bewley model has no heterogeneity in trading technologies. All agents are buy-and-hold traders who hold the market. Note that this is the optimal portfolio choice given that there are no non-participants. We also consider a LP (limited participation) version of the model with 50% of wealth held by active traders and 50% of wealth held by non-participants. However, they make up 35% and 65% of the population respectively.

The top panel in Table 4 reports the summary statistics for the Bewley model and the HTT model. We contrast the model’s predictions with the same statistics from the 2004 SCF for US households. The Gini coefficient in the data is .727 (SCF, 2001). Our model produces a Gini coefficient of .56. The model without heterogeneous trading opportunities produces a Gini coefficient of .47. So, the heterogeneity in trading opportunities bridges half of the gap with the data, by producing fatter tails and a more skewed distribution. The skewness of the wealth distribution increases from .8 to 2.78 (compared to 3.6 in the data) while the kurtosis increases from 3.1 to 14.5. (compared to 15.9 in the data).

The 75/25 ratio increases to 7.49 from 4.78 while the 80/20 ratio increases to 9.79 from 6.39. The 90/10 ratio increases to 188 from 82. However, the HTT model still falls well short of the data. The poor households accumulate too much wealth in the model compared to the data. This discrepancy is not surprising given that households have no life-cycle motive for borrowing or saving. However, the model does quite well in matching the right tail of the wealth distribution in the data.

Implications for the Asset Share Distribution  Finally, we turn to the asset class share distribution, and we check whether our model can replicate the distribution of asset shares in the data. We also consider the LP (limited participation) version of our economy with 50% non-participants and 50% active traders. Table 4 shows the equity share (as a fraction of the...
household portfolio) at different percentiles of the wealth distribution in the model and the data. In the data, we rank households in terms of net worth and we backed out their equity holding as a fraction of net wealth. We include private businesses in equity. In the Bewley model, all households hold the market portfolio. Hence, the Bewley model over-predicts the equity shares for all households below the 80% and under-predicts for the wealthier households. The LP model model tends to over-predict equity shares below the 95-th percentile, and it under-predicts for the higher percentiles. Clearly, the HTT model delivers a closer match of the equity share distribution in the data than any of the competing models.

6.2 Limited Participation

To disentangle the effects of heterogeneity in trading technologies from the effects of limited participation, Cases (3) and (4) report the same moments of asset prices that obtain when all stock market participants are active traders. Hence, we eliminate the heterogeneity in trading technologies among market participants altogether. This is the standard case considered in the literature on limited participation (see e.g. Gomes and Michaelides (2008)). By comparing case (1) and (3) ((2) and (4) respectively), we get a precise measure of the impact of the heterogeneity in trading technologies. The impact is substantial. In case (1), the equity premium drops 191 basis points when we replace the 20% buy-and-hold traders with active traders. In other words, 53% of the increase in the equity premium (relative to the RA case) is due to the heterogeneity in trading technologies, not limited participation. The market price of risk decreases from .44 to .32 and its volatility drops from 3.3% to 1.4%. In case (2), the drop in the equity is 220 basis points (compare to case (4)). The equity premium is only 68 basis points higher than the RA case. In this case, the heterogeneity accounts for 76% of the increase in the equity premium.

6.3 Composition of the Passive Trader Pool

Clearly, the composition of the pool of participants (active vs buy-and-hold investors) matters for the size of the risk premium. However, the exact composition of the pool of passive traders is much less important. To make this point, Table 5 fixes the average equity holdings of all passive traders at the level in the benchmark model reported in case (1) in Table 1 but it changes the composition of the passive trader pool. This experiment is labeled ‘1x’. In this benchmark case, the average passive trader holds 5.56% in equity: 77% of passive traders (non-participants) hold no equity while 23% (buy-and-hold traders) hold 25% equity. In the IID economy (left panel in 5), changes in the composition of the pool have only small effects on risk premia. What matters for risk premia is the average equity holdings of the passive traders. The equity risk premium is roughly constant across Case (a)-Case (b).
We also double the level of equity holdings of the passive traders. This experiment is labeled ‘2x’. The equity risk premium declines from 6.81% in the ‘1x’ case to 5.58% in the ‘2x’ case. However, interestingly, the volatility of risk premia seems largely unaffected by the increase in average equity participation. In fact, in case (a), the benchmark case, the volatility of the market price of risk increases from 3.9% to 4.5%. Passive traders’s demand for risky assets is inelastic with respect to variation in state prices. Hence, the required variation in the size of state price adjustments to clear asset markets do not decline as equity holdings increase.

6.4 Non-IID Economy

Finally, in another robustness check, we relax the i.i.d. assumption for aggregate consumption growth and we allow for counter-cyclical cross-sectional variation in labor income. The aggregate consumption growth dynamics match those in Mehra and Prescott (1985): we set the first-order autocorrelation to −.16. The other moments of aggregate consumption growth are unchanged. In addition, we allow for a concentration for income risk in recessions, as suggested by Mankiw (1986), Constantinides and Duffie (1996) and documented in the data by Storesletten, Telmer, and Yaron (2004). To determine the idiosyncratic shocks in this case, we follow Alvarez and Jermann (2001) and impose that

\[
\text{std} \left( \ln \eta' | \sigma' = R \right) / \text{std} \left( \ln \eta' | \sigma' = E \right) = 1.88.
\]

We reduce the leverage parameter \( \psi \) from 3 to 2 in this case, because the interest rate variation imputes more volatility to dividend growth and returns. This also implies that the buy-and-hold investor now invests 33% in equities and 66% in the risk-free asset.

Asset Pricing Results  The asset pricing results are reported in the right panel of Table 1. In column (1), we report the results for the RA economy. The negative autocorrelation in aggregate consumption growth imputes volatility to the risk-free rate of about 3% per annum. However, we adjusted the leverage parameter from 3 to 2, and the volatility of stock returns is still about 16% per annum. In the benchmark case (Case (1)), the maximum Sharpe ratio increases from 44% to 50% per annum. The actual Sharpe ratio on equity is .49. More importantly, the negative autocorrelation makes longer bonds risky again, and thus delivers an upward sloping real yield curve. This is not shown in the Table.

Approximation  The quality of the approximation does depend on the properties of aggregate consumption growth and labor income. In the non-IID economy, the size the approximation error statistic \( \sup \text{std}(\log g) \) varies between .75% and 1.08%, about double the size of the errors in the IID economy, mainly because the volatility of the shocks to \( g \) more than doubles. The right panel of Table 2 also reports the forecasting regression results for the non-IID economy. The \( R^2 \) in the forecasting regression for the moments method and our method are almost uniformly lower.
This is partly because for each \((z, z')\) transition, the standard deviation of the aggregate weight growth shocks is much higher than in the IID case. For example, in the low to low transition, the standard deviation of the shocks \(\text{std}(\log g)\) increased from 4.80% in the IID economy to 9.3% in the non-IID economy.

7 Conclusion

To solve a dynamic incomplete markets model populated by agents with different trading technologies, we show that the same consumption sharing rule, which relates the household’s multiplier, its state variable, to its consumption, applies to all households, regardless of their trading technology, even though the multiplier’s dynamics are different for different trading technologies. This allows to derive an expression for state prices as a function of the aggregate multiplier, which is one specific moment of the distribution of multipliers across households and trading technologies. To solve for the equilibrium allocations and market-clearing prices, we simply need to forecast the growth rate of this aggregate multiplier in each aggregate state of the world. In a calibrated version of the model, we show that a truncated version of the history of aggregate shocks does well in forecasting this growth rate.

In the quantitative section of the paper, we calibrate a model with heterogeneity in trading technologies to match the historical average of the risk-free rate and the equity premium. The heterogeneity in trading opportunities that we introduce brings the standard model much closer to matching the asset class share and wealth distribution in the data. The passive traders in our model accumulate much less wealth than the active traders, even though they have identical preferences, simply because the latter are compensated for bearing the residual aggregate risk created by the non-participants. Hence, it is imperative to study the wealth and asset share distribution in a model that generates large and volatile risk premia. However, the heterogeneity in trading opportunities cannot fully account for the lack of wealth accumulation among US households that are part of the middle class.

References

**A Proofs**

- Proof of Corollary 3.1

**Proof.** We know that $E\{\zeta(z^{t+1}, \eta^{t+1})|z^{t+1}\} \leq \zeta(z^t, \eta^t)$. This implies that

$$E\{\zeta^{-1/\alpha}(z^{t+1}, \eta^{t+1})|z^{t+1}\} \geq E\{\zeta(z^{t+1}, \eta^{t+1})|z^{t+1}\}^{-1/\alpha} = \zeta(z^t, \eta^t)^{-1/\alpha}.$$

Assume $h(z^{t+1}) \leq h(z^t)$. Then the risk-sharing rule in (A.3) implies the unconstrained active trader’s consumption share increases over time.

- Proof of proposition 3.1

**Proof.** We have shown that, if interest rates are high enough (i.e. if the present value of the aggregate endowment is finite), any feasible allocation in the sequential economy satisfies the static budget constraints, using the recursive definition of state prices, as well as the static version of the solvency and the measurability constraints. Hence, the sequential equilibrium allocation is feasible in the static economy. It is sufficient to define Lagrangian multipliers for the static budget constraints, solvency constraints and measurability constraints, and verify that these are a saddle. The initial multiplier on the static budget constraint $\chi$ are identical for all households. Subsequently, the cumulative multipliers in each node $(z^t, \eta^t)$ can be constructed recursively from the prices

$$\beta^t u'(c(z^t, \eta^t)) = P(z^t)\zeta(z^t, \eta^t)$$

(A.1)
These multipliers are non-negative because state prices are. The saddle point property follows. We define the Lagrangian as follows:

\[
L(\{\bar{c}, \{\bar{a}_t\}, \{\gamma\}, \{\bar{\pi}\}, \{\bar{c}\}) = \sum_{t=1}^{\infty} \beta^{t} \sum_{(z^t, \eta^t)} u(c(z^t, \eta^t)) \pi(z^t, \eta^t) + \lambda \left\{ \sum_{t \geq 1} \sum_{(z^t, \eta^t)} \tilde{P}(z^t, \eta^t) \left[ \gamma Y(z^t) \eta_t - \bar{c}(z^t, \eta^t) \right] + a_{-1}(z^0) \right\} \\
+ \sum_{t \geq 1} \sum_{(z^t, \eta^t)} \bar{c}(z^t, \eta^t) \left\{ \sum_{\tau \geq t} \sum_{(z^\tau, \eta^\tau) \geq (z^t, \eta^t)} \tilde{P}(z^\tau, \eta^\tau) \left[ \gamma Y(z^\tau) \eta_\tau - \bar{c}(z^\tau, \eta^\tau) \right] + \tilde{P}(z^t, \eta^t) a_{t-1}(z^t, \eta^{t-1}) \right\} \\
+ \sum_{t \geq 1} \sum_{(z^t, \eta^t)} \bar{c}(z^t, \eta^t) \left\{ -M_d(z^t, \eta^t) \tilde{P}(z^t, \eta^t) - \sum_{\tau \geq t} \sum_{(z^\tau, \eta^\tau) \geq (z^t, \eta^t)} \tilde{P}(z^\tau, \eta^\tau) \left[ \gamma Y(z^\tau) \eta_\tau - \bar{c}(z^\tau, \eta^\tau) \right] \right\},
\]

First, note that the \( \zeta \) we constructed minimizes \( L(\{\bar{c}, \{\bar{a}_t\}, \{\gamma\}, \{\bar{\pi}\}, \{\bar{c}\}) \) for the sequential equilibrium allocations \( \{c\} \) because the multipliers are zero when the constraints do not bind, by construction from the sequential equilibrium allocations. Define

\[
L(\{\bar{c}, \{\zeta\}) = \sum_{t=1}^{\infty} \beta^{t} \sum_{(z^t, \eta^t)} u(\bar{c}(z^t, \eta^t)) \pi(z^t, \eta^t) - \sum_{t \geq 1} \sum_{(z^t, \eta^t)} \tilde{P}(z^t, \eta^t) \left[ \zeta(z^t, \eta^t)\bar{c}(z^t, \eta^t) \right],
\]

where we have left out the rest of the Lagrangian that does not depend on \( \{\bar{c}\} \). To show that this is a saddle point, it only remains to show that the sequential equilibrium allocations \( \{c\} \) maximize the Lagrangian \( L(\{\bar{c}, \{\zeta\}) \leq L(\{c\}; \{\zeta\}) \), which follows directly from the first order condition in (A.1) and from the fact that by concavity and differentiability we have that \( u(\bar{c}) \leq u(c) + u'(c)\bar{c} - c \). To derive the saddle point result, it is sufficient to substitute the right hand side of this last equation into the Lagrangian. 

\[\square\]

- Proof of Proposition 3.2

Proof. Condition (3.6) implies that \( c(z^t, \eta^t) = u'^{-1} [\beta^{-t} \zeta(z^t, \eta^t) P(z^t)] \). In addition, the sum of individual consumptions aggregate up to aggregate consumption \( C(z^t) = \sum_{\eta^t} c(z^t, \eta^t) \pi(\eta^t | z^t) \). This implies that the consumption share of the individual with history \( (z^t, \eta^t) \) is

\[
\frac{c(z^t, \eta^t)}{C(z^t)} = \frac{u'^{-1} [\beta^{-t} \zeta(z^t, \eta^t) P(z^t)]}{\sum_{\eta^t} u'^{-1} [\beta^{-t} \zeta(z^t, \eta^t) P(z^t)] \pi(\eta^t | z^t)}, \tag{A.2}
\]
With CRRA preferences, this implies that the consumption share is given by
\[
\frac{c(z^t, \eta^t)}{C(z^t)} = \frac{\zeta(z^t, \eta^t)}{h(z^t)}, \quad \text{where} \quad h(z^t) = \sum_{\eta^t} \zeta(z^t, \eta^t) \pi(\eta^t | z^t).
\]

(A.3)

Hence, the $-1/\alpha^t$th moment of the multipliers summaries risk sharing within this economy. And, with this moment we get a simple linear risk sharing rule with respect to aggregate consumption. Making use of (A.2) and the individual first-order condition, we get that
\[
\beta_t u' \left[ \frac{u't^{-1} [\beta^{-t} \zeta(z^t, \eta^t) P(z^t)]}{\sum_{\eta^t} u't^{-1} [\beta^{-t} \zeta(z^t, \eta^t) P(z^t)] \pi(\eta^t | z^t)} \right] = P(z^t) \zeta(z^t, \eta^t).
\]

If $u^{t-1}$ is homogeneous, which it is with CRRA preferences, then this expression simplifies to
\[
\beta_t u' \left[ \frac{C(z^t)}{\sum_{\eta^t} u't^{-1} [\zeta(z^t, \eta^t)] \pi(\eta^t | z^t)} \right] = P(z^t),
\]

which implies that the ratio of the state prices is given by
\[
\frac{\beta_t u' \left[ \frac{C(z^{t+1})}{\sum_{\eta^t} u't^{-1} [\zeta(z^{t+1}, \eta^{t+1})] \pi(\eta^{t+1} | z^{t+1})} \right]}{P(z^t)} = \frac{P(z^{t+1})}{P(z^t)}.
\]

(A.4)

Given that we are assuming CRRA preferences, this implies the following proposition.

- Proof of proposition 3.3

Proof. First, since the measurability constraints are satisfied for the individual household’s savings function, they also need to be satisfied for the aggregate savings function. So by the LLN:
\[
\frac{A^{bh}(z^{t+1})}{(1 - \gamma)Y(z^{t+1}) + \varpi(z^{t+1})} = \frac{A^{bh}(z^t, \tilde{z}_{t+1})}{(1 - \gamma)Y(z^t, \tilde{z}_{t+1}) + \varpi(z^t, \tilde{z}_{t+1})}
\]

where we have used the fact that the denominator is measurable w.r.t. $z^t$. Note that $\sum_k A^k(z^{t+1}) = - [(1 - \gamma)Y(z^t, \tilde{z}_{t+1}) + \varpi(z^t, \tilde{z}_{t+1})]$. Hence the ratio $A^{bh}(z^{t+1})/ \sum_k A^k(z^{t+1}) = \kappa(z^t)$ cannot not depend on $z_t$, because of the measurability condition.

- Proof of proposition 3.4

Proof. For non-participant traders $j = np$, $A^j(z^t)$ cannot not depend on $z_t$, because of the measurability condition.

Notes: Parameters setting: $\gamma = 5$, $\beta = 0.95$, collateralized share of income is 0.1. The simulation moments are generated by 10000 draws from an economy with 3000 agents. The IID Economy reports results for the Benchmark calibration of idiosyncratic shocks and i.i.d. calibration of aggregate shocks. The non-IID Economy reports results for the STY calibration of idiosyncratic shocks and MP calibration of aggregate shocks. Reports the moments of asset prices for the RA (Representative Agent) economy, for the HTT (Heterogeneous Trading Technology) economy, the LP (limited participation) economy and for the data. We use post-war US annual data for 1946-2005. The market return is the CRSP value weighted return for NYSE/NASDAQ/AMEX. We use the Fama risk-free rate series from CRSP (average 3-month yield). To compute the standard deviation of the risk-free rate, we compute the annualized standard deviation of the ex post real monthly risk-free rate. The welfare cost is the percentage of consumption that the non-participant (buy-and-hold investor) is willing to give up to become an active trader. The last row (sup $\sigma[\log g]$/%) reports the maximal coefficient of variation across all aggregate truncated histories of the actual aggregate multiplier growth rate $g$ in percentages.

Notes: Parameters setting: $\gamma = 5$, $\beta = 0.95$, collateralized share of income is 0.1. The simulation moments are generated by 10000 draws from an economy with 3000 agents. Benchmark calibration of idiosyncratic shocks and aggregate shocks. The wealth data are from the 2004 SCF. The HTT model has 10% active traders, 40% buy-and-hold traders and 50% non-participants. The Bewley model has 100% buy-and-hold traders. The LP model has 50% non-participants and 50% active traders. The income data are from the 2004 SCF. The wealth data are from the 2004 SCF. The equity share reported is the share of equity (including private business) as a fraction of net worth. The data are from the 2004 SCF.

Notes: Parameters setting: $\gamma = 5, \beta = 0.95$, collateralized share of income is 0.1. The simulation moments are generated by 10000 draws from an economy with 3000 agents. The IID Economy reports results for the Benchmark calibration of idiosyncratic shocks and i.i.d. calibration of aggregate shocks. The non-IID Economy reports results for the STY calibration of idiosyncratic shocks and MP calibration of aggregate shocks. Reports the moments of asset prices for the HTT (Heterogeneous Trading Technology) economy. The ‘1x’ case fixes the equity holdings of all passive traders at 5.6 %. The ‘2x’ case fixes the equity holdings of all passive traders at 11.2 %
Figure 1: Conditional Risk Premium and Market Price of Risk

Notes: Market Segmentation Case (1): 10% in active, 20% buy-and-hold and 70% non-participants. Parameters setting: $\gamma = 5$, $\beta = 0.95$, collateralized share of income is 0.1. Plot of 100 draws from an economy with 3000 agents. Benchmark calibration of idiosyncratic shocks and IID calibration of idiosyncratic shocks. The shaded areas indicate low aggregate consumption growth states.
